Radiosurgery has place in veterinary dentistry

**Q.** I have heard a lot about radiosurgery in human dentistry. How does it apply to animal dentistry? Is it safe?

**A.** Radiosurgery is very safe and has multiple uses in veterinary dentistry. High frequency radio waves of 3.0-4.0 MHz produce a pressureless incision with minimal thermal and mechanical tissue trauma. With radiosurgery there is the virtual elimination of bleeding allowing a clear surgical field.

There are four radiosurgery waveforms used in dentistry. The fully filtered waveform, with minimal lateral heat, is used most frequently when incisions are close to bone. This waveform is used in biopsy, frenectomies, mucogingival surgery and the troughing procedure.

The troughing procedure is used for widening of the sulcus for a crown impression in subgingival fixed prosthodontics.

The fully rectified waveform provides cutting with hemostasis.

With this waveform resultant tissue shrinkage and some lateral heat don’t make it a choice when working near bone. It is used in gingivoplasty, epulis removal, and pericoronial flap removal.

The partially rectified waveform is used to produce hemostasis.

It should not be used for coagulation close to bone because of significant lateral heat and tissue shrinkage. The main uses are coagulation of soft tissue and desensitizing cementum and dentin with cervical erosions.

The final waveform, the fulguration waveform, produces a dehydrating effect as it causes the greatest amount of lateral heat. The spear shaped electrode is placed about 0.5 mm above the surface of the tissue. A spark is produced when the current is activated leading to superficial destruction and coagulation. It is also called the spark-gap technique and is frequently used for the destruction of fistulous tracts, destruction of cyst remnants and hemostasis in osseous surgery.

There are a plethora of radiosurgery electrode tips available.

The straight wire, loop and ball are the three most commonly used.

Whether for periodontal surgery (gingivoplasty and flap surgery) or in prosthodontic (subgingival impressions) soft tissue preparation, radiosurgery is an invaluable tool. There are four radiosurgery waveforms used in dentistry. The fully filtered waveform, with minimal lateral heat, is used most frequently when incisions are close to bone. This waveform is used in biopsy, frenectomies, mucogingival surgery and the troughing procedure.
